## 1 LSTMs

These notes are based on [1]. LSTMs were developed in order to circumvent the vanishing gradient problem that plagues multi-layered RNNs. LSTMs are equipped with a long-term memory and a short-term working memory.

Let  $x_t \in \mathbb{R}^p$  denote the input at time t; let  $\lim_{t \to \infty} \mathbb{R}^d$  and  $\lim_{t \to \infty} \mathbb{R}^d$  denote, respectively, the long-term memory and the working memory available to the LSTM cell at time t.

**Updating the long-term memory.** In order to update the long-term memory at step t, the LSTM first figures out what to remember from the long-term memory of the last step t-1.

$$\operatorname{rem}_{t} = \sigma \left( W_{r} \cdot x_{t} + U_{r} \cdot \operatorname{wm}_{t-1} + b_{r} \right). \tag{1}$$

This is accomplished using a one-layer neural network with a sigmoid activation function that estimates the weight matrices  $W_r \in \mathbf{R}^{p \times d}$ ,  $U_r \in \mathbf{R}^{d \times d}$  and the bias vector  $b_r \in \mathbf{R}^d$ . Since the activation function is sigmoid, the components of  $\operatorname{rem}_t$  are between 0 and 1. If a component is closer to 1, we would want to remember it; if it is close to 0, then we want to forget it.

It next calculates a "candidate" vector to add to its long-term memory. This is done using a single-layer neural network with a tanh activation function. Denote this candidate by ltm'<sub>r</sub>.

$$\operatorname{ltm}_{t}' = \sigma \left( W_{l} \cdot x_{t} + U_{l} \cdot \operatorname{wm}_{t-1} + b_{l} \right). \tag{2}$$

As usual,  $W_l \in \mathbb{R}^{p \times d}$ ,  $U_l \in \mathbb{R}^{d \times d}$  and  $b_l \in \mathbb{R}^d$ .

Not all parts of this candidate vector may be worth remembering. As such, a save $_t$  vector is created using another single-layer neural network with a sigmoid activation function.

$$save_t = \sigma(W_s \cdot x_t + U_s \cdot wm_{t-1} + b_s). \tag{3}$$

The dimensions of the weight matrices  $W_s$ ,  $U_s$  and the bias vector  $b_s$  are such that save  $t \in \mathbb{R}^d$ . Now the long-term component of the cell is computed using:

$$\operatorname{ltm}_{t} = \operatorname{rem}_{t} \odot \operatorname{ltm}_{t-1} + \operatorname{save}_{t} \odot \operatorname{ltm}'_{t}, \tag{4}$$

where  $\odot$  represents component-wise multiplication of the d-dimensional vectors.

**Updating the working memory.** To do this, the LSTM first calculates what parts of the long-term memory it currently wants to focus on. It uses another single-layer neural network with a sigmoid activation to calculate focus<sub>t</sub>  $\in \mathbb{R}^d$ .

$$focus_t = \sigma \left( W_f \cdot x_t + U_f \cdot wm_{t-1} + b_f \right). \tag{5}$$

It then updates its working memory using:

$$wm_t = focus_t \odot tanh(ltm_t). \tag{6}$$
